EXPRESSIVENESS AND CLOSURE PROPERTIES FOR QUANTITATIVE LANGUAGES

KRISHNENDU CHATTERJEE, LAURENT DOYEN, AND THOMAS A. HENZINGER

Abstract. Weighted automata are nondeterministic automata with numerical weights on transitions. They can define quantitative languages $L$ that assign to each word $w$ a real number $L(w)$. In the case of infinite words, the value of a run is naturally computed as the maximum, limsup, liminf, limit-average, or discounted-sum of the transition weights. The value of a word $w$ is the supremum of the values of the runs over $w$. We study expressiveness and closure questions about these quantitative languages.

We first show that the set of words with value greater than a threshold can be non-$\omega$-regular for deterministic limit-average and discounted-sum automata, while this set is always $\omega$-regular when the threshold is isolated (i.e., some neighborhood around the threshold contains no word). In the latter case, we prove that the $\omega$-regular language is robust against small perturbations of the transition weights.

We next consider automata with transition weights 0 or 1 and show that they are as expressive as general weighted automata in the limit-average case, but not in the discounted-sum case.

Third, for quantitative languages $L_1$ and $L_2$, we consider the operations $\max(L_1, L_2)$, $\min(L_1, L_2)$, and $1 - L_1$, which generalize the boolean operations on languages, as well as the sum $L_1 + L_2$. We establish the closure properties of all classes of quantitative languages with respect to these four operations.
1. Introduction

A boolean language $L$ can be viewed as a function that assigns to each word $w$ a boolean value, namely, $L(w) = 1$ if the word $w$ belongs to the language, and $L(w) = 0$ otherwise. Boolean languages model the computations of reactive programs. The verification problem “does the program $A$ satisfy the specification $B$?” then reduces to the language-inclusion problem “is $L_A \subseteq L_B$?”, or equivalently, “is $L_A(w) \leq L_B(w)$ for all words $w$?”, where $L_A$ represents the behaviors of the program, and $L_B$ contains all behaviors allowed by the specification. When boolean languages are defined by finite automata, this framework is called the automata-theoretic approach to model-checking [VW86].

In a natural generalization of this framework, a cost function assigns to each word a real number instead of a boolean value. For instance, the value of a word (or behavior) can be interpreted as the amount of some resource (e.g., memory consumption, or power consumption) that the program needs to produce it, and a specification may assign a maximal amount of available resource to each behavior, or bound the long-run average available use of the resource.

Weighted automata over semirings (i.e., finite automata with transition weights in a semiring structure) have been used to define cost functions, called formal power series for finite words [Sch61, KS86] and $\omega$-series for infinite words [CK94, DK03, ÆK04]. In [CDH08], we study new classes of cost functions using operations over rational numbers that do not form a semiring. We call them quantitative languages. We set the value of a (finite or infinite) word $w$ as the supremum value of all runs over $w$ (if the automaton is nondeterministic, then there may be many runs over $w$), and the value of a run $r$ is a function of the (finite or infinite) sequence of weights that appear along $r$. We consider several functions, such as Max and Sum of weights for finite runs, and Sup, LimSup, LimInf, limit-average, and discounted sum of weights for infinite runs. For example, peak power consumption can be modeled as the maximum of a sequence of weights representing power usage; energy use can be modeled as the sum; average response time as the limit-average [CCH+05, CdHS03]. Quantitative languages can also be used to specify and verify reliability requirements: if a special symbol $\perp$ is used to denote failure and has weight 1, while the other symbols have weight 0, one can use a limit-average automaton to specify a bound on the rate of failure in the long run [CGH+08]. The discounted sum can be used to specify that failures happening later are less important than those happening soon [JAHM03].

The quantitative language-inclusion problem “given two automata $A$ and $B$, is $L_A(w) \leq L_B(w)$ for all words $w$?” can then be used to check, say, if for each behavior, the peak power used by the system lies below the bound given by the specification; or if for each behavior, the long-run average response time of the system lies below the specified average response requirements. In [CDH08], we showed that the quantitative language-inclusion problem is PSPACE-complete for Sup-, LimSup-, and LimInf-automata, while the decidability is unknown for (nondeterministic) limit-average and discounted-sum automata. We also compared the expressive power of the different classes of quantitative languages and showed that nondeterministic automata are strictly more expressive than deterministic automata in the limit-average and discounted-sum cases.

In this paper, we investigate alternative ways of comparing the expressive power of weighted automata. First, we consider the cut-point languages of weighted automata, a notion borrowed from the theory of probabilistic automata [Rab63]. Given a threshold $\eta \in \mathbb{R}$, the cut-point language of a quantitative language $L$ is the set of all words $w$ with
value $L(w) \geq \eta$, thus a boolean language. We show that deterministic limit-average and discounted-sum automata can define cut-point languages that are not $\omega$-regular. Note that there also exist $\omega$-regular languages that cannot be expressed as a cut-point language of a limit-average or discounted-sum automaton \cite{CDH08}. Then, we consider the special case where the threshold $\eta$ is isolated, meaning that there is no word with a value in the neighborhood of $\eta$. We argue that isolated cut-point languages are robust, by showing that they remain unchanged under small perturbations of the transition weights. Furthermore, we show that every discounted-sum automaton with isolated cut-point defines an $\omega$-regular language, and the same holds for deterministic limit-average automata. This question is open for nondeterministic limit-average automata. Finally, we consider a boolean counterpart of limit-average and discounted-sum automata in which all transitions have weight 0 or 1. Of special interest is a proof that for every limit-average automaton with rational weights in the interval $[0,1]$ there is an equivalent limit-average automaton with boolean weights. Therefore, the restriction to boolean weights does not change the class of quantitative languages definable by limit-average automata; on the other hand, we show that it reduces the expressive power of discounted-sum automata.

In the second part of this paper, we study the closure properties of quantitative languages. It is natural and convenient to decompose a specification or a design into several components, and to apply composition operators to obtain a complete specification. We consider a natural generalization of the classical operations of union, intersection, and complement of boolean languages. We define the maximum, minimum, and sum of two quantitative languages $L_1$ and $L_2$ as the quantitative language that assigns $\max(L_1(w), L_2(w))$, $\min(L_1(w), L_2(w))$, and $L_1(w) + L_2(w)$ to each word $w$. The complement $L^c$ of a quantitative language $L$ is defined by $L^c(w) = 1 - L(w)$ for all words $w$.\footnote{One can define $L^c(w) = k - L(w)$ for any rational constant $k$ without changing the results of this paper.} The sum is a natural way of composing two automata if the weights represent costs (e.g., energy consumption). We give other examples in Section 2 to illustrate the composition operators and the use of quantitative languages as a specification framework.

We give a complete picture of the closure properties of the various classes of quantitative languages (over finite and infinite words) under maximum, minimum, complement and sum (see Table 1). For instance, (non)deterministic limit-average automata are not closed under sum and complement, while nondeterministic discounted-sum automata are closed under sum but not under complement. All other classes of weighted automata are closed under

sum. For infinite words, the closure properties of $\text{Sup}$-, $\text{LimSup}$-, and $\text{LimInf}$-automata are obtained as a direct extension of the results for boolean finite automata, while for limit-average and discounted-sum automata, the proofs require the analysis of the structure of the automata cycles and properties of the solutions of polynomials with rational coefficients. Note that the quantitative language-inclusion problem “is $L_A(w) \leq L_B(w)$ for all words $w$?” reduces to closure under sum and complement, because it is equivalent to the question of the non-existence of a word $w$ such that $L_A(w) + L_B(w) > 1$, an emptiness question which is decidable for all classes of quantitative languages [CDH08]. Also note that deterministic limit-average and discounted-sum automata are not closed under maximum, which implies that nondeterministic automata are strictly more expressive in these cases (because the maximum can be obtained by an initial nondeterministic choice).

Related work. Functions such as limit-average (or mean-payoff) and discounted sum have been studied extensively in the branching-time context of game theory [Sha53, EM79, Con92, ZP96, CdHS03]. It is therefore natural to use the same functions in the linear-time context of languages and automata.

Weighted automata with discounted sum have been considered in [DR07], with multiple discount factors and a boolean acceptance condition (Muller or Büchi); they are shown to be equivalent to a weighted monadic second-order logic with discounting. Several other works have considered quantitative generalizations of languages, over finite words [DG07], over trees [DKR08], or using finite lattices [GC03], but none of these works has addressed the expressiveness questions and closure properties for quantitative languages that are studied here.

The lattice automata of [KL07] map finite words to values from a finite lattice. The lattice automata with Büchi condition are analogous to our $\text{LimSup}$ automata, and their closure properties are established there. However, the other classes of quantitative automata ($\text{Sum}$, limit-average, discounted-sum) are not studied there as they cannot be defined using lattice operations and finite lattices.

## 2. Quantitative Languages

A quantitative language $L$ over a finite alphabet $\Sigma$ is either a mapping $L : \Sigma^+ \rightarrow \mathbb{R}$ or a mapping $L : \Sigma^\omega \rightarrow \mathbb{R}$, where $\mathbb{R}$ is the set of real numbers.

**Weighted automata.** A weighted automaton is a tuple $A = \langle Q, q_I, \Sigma, \delta, \gamma \rangle$, where

- $Q$ is a finite set of states, $q_I \in Q$ is the initial state, and $\Sigma$ is a finite alphabet;
- $\delta \subseteq Q \times \Sigma \times Q$ is a finite set of labelled transitions. We assume that $\delta$ is total, i.e., for all $q \in Q$ and $\sigma \in \Sigma$, there exists $q'$ such that $(q, \sigma, q') \in \delta$;
- $\gamma : \delta \rightarrow \mathbb{Q}$ is a weight function, where $\mathbb{Q}$ is the set of rational numbers. We assume that rational numbers are encoded as pairs of integers in binary.

We say that $A$ is deterministic if for all $q \in Q$ and $\sigma \in \Sigma$, there exists $(q, \sigma, q') \in \delta$ for exactly one $q' \in Q$. We sometimes call automata nondeterministic to emphasize that they are not necessarily deterministic.

A run of $A$ over a finite (resp. infinite) word $w = \sigma_1 \sigma_2 \ldots$ is a finite (resp. infinite) sequence $r = q_0 \sigma_1 q_1 \sigma_2 \ldots$ of states and letters such that (i) $q_0 = q_I$, and (ii) $(q_i, \sigma_{i+1}, q_{i+1}) \in \delta$ for all $0 \leq i < |w|$. We denote by $\gamma(r) = v_0 v_1 \ldots$ the sequence of weights that occur in $r$ where $v_i = \gamma(q_i, \sigma_{i+1}, q_{i+1})$ for all $0 \leq i < |w|$. 

Given a value function $\text{Val} : \mathbb{Q}^+ \rightarrow \mathbb{R}$ (resp. $\text{Val} : \mathbb{Q}^\omega \rightarrow \mathbb{R}$), we say that the $\text{Val}$-automaton $A$ defines the quantitative language $L_A$ such that for all $w \in \Sigma^+$ (resp. $w \in \Sigma^\omega$):

$$L_A(w) = \sup \{ \text{Val}(\gamma(r)) \mid r \text{ is a run of } A \text{ over } w \}.$$  

We assume that $\text{Val}(v)$ is bounded when the numbers in $v$ are taken from a finite set (namely, the set of weights in $A$), and since weighted automata are total, every word has at least one run and thus $L_A(w)$ is not infinite.

We consider the following value functions to define quantitative languages (they all satisfy the boundedness assumption above). Given a finite sequence $v = v_1 \ldots v_n$ of rational numbers, define

- $\text{Max}(v) = \max \{ v_i \mid 1 \leq i \leq n \}$;
- $\text{Last}(v) = v_n$;
- $\text{Sum}(v) = \sum_{i=1}^{n} v_i$;

Given an infinite sequence $v = v_0v_1 \ldots$ of rational numbers, define

- $\text{Sup}(v) = \sup \{ v_n \mid n \geq 0 \}$;
- $\text{LimSup}(v) = \limsup_{n \to \infty} v_n = \lim_{n \to \infty} \sup \{ v_i \mid i \geq n \}$;
- $\text{LimInf}(v) = \liminf_{n \to \infty} v_n = \lim_{n \to \infty} \inf \{ v_i \mid i \geq n \}$;
- $\text{LimAvg}(v) = \liminf_{n \to \infty} \frac{1}{n} \cdot \sum_{i=0}^{n-1} v_i$;
- for $0 < \lambda < 1$, $\text{Disc}_\lambda(v) = \sum_{i=0}^{\infty} \lambda^i \cdot v_i$;

Intuitively for a sequence $v = v_0v_1 \ldots$ of rational numbers from the finite set $V$, the $\text{Sup}$ function chooses the maximal number that appear in $v$; the $\text{LimSup}$ function chooses the maximal number that appear infinitely often in $v$; the $\text{LimInf}$ function chooses the minimal number that appear infinitely often in $v$; the $\text{LimAvg}$ functions gives the long-run average of the numbers in $v$; and the $\text{Disc}_\lambda$ gives the discounted sum of the numbers in $v$. Note that $\text{LimAvg}(v)$ is defined using lim inf and is therefore well-defined; all results of this paper hold also if the limit-average of $v$ is defined instead as $\limsup_{n \to \infty} \frac{1}{n} \cdot \sum_{i=0}^{n-1} v_i$. One could also consider the value function $\inf \{ v_n \mid n \geq 0 \}$ and obtain results analogous to the $\text{Sup}$ value function. Note that the classical finite-word acceptance condition of finite automata (defining regular languages) can be encoded by $\text{Last}$-automata with weights in $\{0, 1\}$, while Büchi and coBüchi automata are special cases of respectively $\text{LimSup}$- and $\text{LimInf}$-automata, with weights in $\{0, 1\}$. The class of languages defined by nondeterministic Büchi automata is called $\omega$-regular.

**Significance of value functions.** The value functions provide natural generalizations of the classical boolean languages, they are complete for different levels of the Borel hierarchy, and they have been well studied in the context of game theory.

(1) The $\text{Sup}$ value function is the natural quantitative generalization of the reachability condition and is complete for the first level of the Borel hierarchy ($\Sigma_1$ complete).
The $\text{LimSup}$ and $\text{LimInf}$ objectives are the natural quantitative generalizations of the classical Büchi and coBüchi conditions. Moreover, the $\text{LimSup}$ and $\text{LimInf}$ objectives are complete for the second level of the Borel hierarchy, and hence important and canonical quantitative functions ($\text{LimSup}$ and $\text{LimInf}$ objectives are $\Pi_2$ and $\Sigma_2$ complete, respectively) (see [Wad84 MP92] for details related to completeness and reducibility of objectives in the Borel hierarchy).

The $\text{LimAvg}$ and $\text{Disc}_\lambda$ value functions have been studied in many different contexts in game theory. Discounted functions on graph games were introduced in the seminal work of Shapley [Sha53], and have been extensively studied in economics. Discounted conditions have also been studied for discounting the future in systems theory [dAHM03]. The $\text{LimAvg}$ function has also been studied extensively in the context of games on graphs: the works of Everett [Eve57], Liggett-Lippman [LL69], Hopfman-Karp [HK66], Ehrenfeucht-Mycielski [EM79], Mertens-Neyman [MN81], Zwick-Paterson [ZP96] have studied different classes of games with $\text{LimAvg}$ objective. Also see the books [FV97 Put94] for applications of discounted and limit-average value functions in the context of games on graphs. Moreover, the $\text{LimAvg}$ value function is complete for the third level of the Borel hierarchy ($\Pi_3$-complete) [Cha07a].

Hence the value functions considered are classical, canonical, and well-studied in the linear-time framework of weighted automata.

**Notation.** Classes of weighted automata over infinite words are denoted with acronyms of the form $xy$ where $x$ is either N(ondeterministic), D(eterministic), or $N/D$ (when deterministic and nondeterministic automata have the same expressiveness), and $y$ is one of the following: $\text{Sup}$, $\text{LSup}$($\text{LimSup}$), $\text{LinF}$($\text{LimInf}$), $\text{LAvg}$($\text{LimAvg}$), or $\text{Disc}$. For Büchi and coBüchi condition, we use BW and CW respectively.

**Reducibility.** A class $\mathcal{C}$ of weighted automata is reducible to a class $\mathcal{C}'$ of weighted automata if for every $A \in \mathcal{C}$ there exists $A' \in \mathcal{C}'$ such that $L_A = L_{A'}$, i.e., $L_A(w) = L_{A'}(w)$ for all (finite or infinite) words $w$. In particular, a class of weighted automata can be determinized if it is reducible to its deterministic counterpart. Reducibility relationships for (non)deterministic weighted automata are given in [CDH08].

**Composition.** Given two quantitative languages $L$ and $L'$ over $\Sigma$, and a rational number $c$, we denote by $\max(L, L')$ (resp. $\min(L, L')$, $L + L'$, $c + L$, and $cL$) the quantitative language that assigns $\max\{L(w), L'(w)\}$ (resp. $\min\{L(w), L'(w)\}$, $L(w) + L'(w)$, $c + L(w)$, and $c \cdot L(w)$) to each word $w \in \Sigma^+$ (or $w \in \Sigma^\omega$). We say that $c + L$ is the shift by $c$ of $L$ and that $cL$ is the scale by $c$ of $L$. The language $1 - L$ is called the complement of $L$. The max, min and complement operators for quantitative languages generalize respectively the union, intersection and complement operator for boolean languages. For instance, De Morgan’s laws hold (the complement of the max of two languages is the min of their complement, etc.) and complementing twice leave languages unchanged.

**Example 1.** We consider a simple illustration of the use of limit-average automata to model the energy consumption of a motor. The automaton $B$ in Figure 1(b) specifies the maximal energy consumption to maintain the motor on or off, and the maximal consumption for a mode change. The specification abstracts away that a mode change can occur smoothly with the slow command. A refined specification $A$ is given in Figure 1(a) where the effect
of slowing down is captured by a third state. One can check that $L_A(w) \leq L_B(w)$ for all words $w \in \{\text{on}, \text{off}, \text{slow}\}^\omega$. Given two limit-average automata that model the energy consumption of two different motors, one needs to define composition operations for weighted automata to obtain the maximal, minimal, and sum of the average energy consumption of the motors.

**Example 2.** Consider an investment of 100 dollars that can be made in two banks $A_1$ and $A_2$ as follows: (a) 100 dollars to bank $A_1$, (b) 100 dollars to bank $A_2$, or (c) 50 dollars to bank $A_1$ and 50 dollars to bank $A_2$. The banks can be either in a good state (denoted $G_1$, $G_2$) or in a bad state (denoted $B_1$, $B_2$). If it is in a good state, then $A_1$ offers 8% reward while $A_2$ offers 6% reward. If it is in a bad state, then $A_1$ offers 2% reward while $A_2$ offers 4% reward. The change of state is triggered by the input symbols $b_1$, $b_2$ (from a good to a bad state) and $g_1$, $g_2$ (from a bad to a good state). The rewards received earlier weight more than rewards received later due to inflation represented by the discount factor. The automata $A_1$ and $A_2$ in Figure 2 specify the behavior of the two banks for an investment of 100 dollars, where the input alphabet is $\{g_1, b_1\} \times \{g_2, b_2\}$ (where the notation $(g_1, \cdot)$ represents the two letters $(g_1, g_2)$ and $(g_1, b_2)$, and similarly for the other symbols). If 50 dollars are invested in each bank, then we obtain automata $C_1$ and $C_2$ from $A_1$ and $A_2$ where each reward is halved. The combined automaton is obtained as the composition of $C_1$ and $C_2$ under the sum operator.

### 3. Expressiveness Results

The expressive power of weighted automata can be compared by mean of the reducibility relation, saying that a class $C$ of weighted automata is at least as expressive as a class $C'$ if every quantitative language definable by some automaton in $C'$ is also definable by some automaton in $C$. The comparison includes boolean languages, considering them as a special case of quantitative languages of the form $L : \Sigma^\omega \rightarrow \{0, 1\}$. It was shown in [CDH08] that a wide variety of classes of quantitative languages can be defined by the different types of
weighted automata, depending on the value function and whether they are deterministic or not. This contrasts with the situation for boolean languages where most of the classes of automata define \( \omega \)-regular languages. In this section, we investigate alternative ways of comparing the expressive power of weighted automata and of classical finite automata. First, we use the cut-point languages of weighted automata to compare with the class of \( \omega \)-regular languages, and then we use weighted automata with boolean weights, i.e., all transitions have weight 0 or 1, to compare with general weighted automata.

3.1. Cut-point languages. Let \( L \) be a quantitative language over infinite words and let \( \eta \in \mathbb{R} \) be a threshold. The cut-point language defined by \((L, \eta)\) is the (boolean) language

\[
L \geq \eta = \{ w \in \Sigma^\omega \mid L(w) \geq \eta \}.
\]

Cut-point languages for finite words are defined analogously. They have been first defined for probabilistic automata [Rab63], then generalized to inverse image recognition for semiring automata over finite words (see e.g. [KS86, CM00]). It is easy to see that the cut-point languages of Max- and Last-automata are regular (they have the same acceptance condition as finite automata), those of Sum-automata are context-free (using a stack to simulate accumulated weights), and those of Sup-, LimSup-, and LimInf-automata are \( \omega \)-regular (they have the same acceptance condition as Büchi and coBüchi automata).

We show that the classes of cut-point languages definable by (non)deterministic limit-average and discounted-sum automata are incomparable with the \( \omega \)-regular languages. One direction of this result follows from Theorem 3.1, and the other direction follows from [CDH08, Theorems 13 and 14] where \( \omega \)-regular languages are given that are not definable as cut-point language of nondeterministic limit-average and discounted-sum automata.

**Theorem 3.1.** There exist deterministic limit-average and discounted-sum automata whose cut-point language is not \( \omega \)-regular.

**Proof.** Consider the alphabet \( \Sigma = \{a, b\} \), and consider the languages \( L_1 \) that assigns to each word its long-run average number of \( a \)'s, and \( L_2 \) that assigns the discounted sum of \( a \)'s. Note that \( L_1 \) is definable by a deterministic limit-average automaton, and \( L_2 \) by a deterministic discounted-sum automaton. It was shown in [Cha07b] that the cut-point language \( L_1^{\geq 1} \) is complete for the third level of the Borel hierarchy, and therefore is not \( \omega \)-regular. We show that \( L_2^{\geq 1} \) is not \( \omega \)-regular.

Given a finite word \( w \in \Sigma^* \), let \( v_a(w) = \sum_{i|w_i=a} \lambda^{i-1} \) be the discounted sum of \( a \)'s in \( w \). We say that \( w \) is ambiguous if \( 1 - \frac{1}{1-\lambda} \leq v_a(w) < 1 \). The ambiguity lies in that some continuations of \( w \) (namely \( w.a^\omega \)) are in \( L_2^{\geq 1} \) and some are not (namely \( w.b^\omega \)). We show

![Diagram](https://via.placeholder.com/150)

(a) 100 dollars invested in bank \( A_1 \).  
(b) 100 dollars invested in bank \( A_2 \).

*Figure 2: The discounted-sum automaton models of two banks.*
that for all $\lambda > \frac{1}{2}$, if $w$ is ambiguous, then either $w.a$ or $w.b$ is ambiguous, which entails that there exists an infinite word $\hat{w}$ all of whose finite prefixes are ambiguous (and $L_2(\hat{w}) = 1$). To do this, assume that $1 - \frac{\lambda^{|w|}}{1-\lambda} < v_a(w) < 1$, and show that either $1 - \frac{\lambda^{i+|w|}}{1-\lambda} < v_a(w.a) < 1$ or $1 - \frac{\lambda^{i+|w|}}{1-\lambda} < v_a(w.b) < 1$. Since $v_a(w.a) = v_a(w) + \lambda^{|w|}$ and $v_a(w.b) = v_a(w)$, we have to show that $1 - \frac{\lambda^{|w|}}{1-\lambda} < v_a(w) < 1 - \lambda^{|w|}$ or $1 - \frac{\lambda^{i+|w|}}{1-\lambda} < v_a(w) < 1$. This holds if $1 - \frac{\lambda^{i+|w|}}{1-\lambda} < 1 - \lambda^{|w|}$, which is equivalent to $\lambda > \frac{1}{2}$.

Now, we show that if there exists a nondeterministic Büchi automaton $A$ for $L_2^{\geq 1}$, then the set of states $S_n$ reached in $A$ by reading the first $n$ letters of $\hat{w}$ (which we denote by $\hat{w}_{[1...n]}$) should be different for each $n$, i.e., $n \neq m$ implies $S_n \neq S_m$. Towards a contradiction, assume that $S_n = S_m$ for $n < m$. Then for all continuations $w' \in \Sigma^\omega$, we have $\hat{w}_{[1...n]} \cdot w' \in L_2^{\geq 1}$ if and only if $\hat{w}_{[1...m]} \cdot w' \in L_2^{\geq 1}$. (\star).

In particular, consider the continuations $\hat{w}_{[n+1...]}$ and $\hat{w}_{[m+1...]}$, and for each $i \geq 1$, let $\gamma^i = v_a(\hat{w}_{[1...i]})$ and $K^i = L_2(\hat{w}_{[i+1...]}$. Then, we have $\gamma^1 + \lambda^i \cdot K^i = 1$, and thus $\gamma^m + \lambda^n \cdot K^n \leq 1$ iff $K^n \leq K^m$. Since either $K^n \leq K^m$ or $K^m \leq K^n$, we have either $L_2(\hat{w}_{[1...m]} \cdot \hat{w}_{[n+1...]} \leq 1$ or $L_2(\hat{w}_{[1...n]} \cdot \hat{w}_{[m+1...]} \leq 1$. By (\star), this implies that either $L_2(\hat{w}_{[1...m]} \cdot \hat{w}_{[n+1...]} = 1$, or $L_2(\hat{w}_{[1...n]} \cdot \hat{w}_{[m+1...]} = 1$, and in both cases since $L_2(\hat{w}) = 1$, we get

$$1 - \gamma^m + 1 - \gamma^n = \frac{\lambda^m}{\lambda^n}.$$ This implies $\lambda^{m-n}(1 - P(\lambda)) = 1 - Q(\lambda)$ where $P(\lambda) = v_a(\hat{w}_{[1...n]})$ and $Q(\lambda) = v_a(\hat{w}_{[1...m]})$ are polynomials of respective degree $n - 1$ and $m - 1$, and with coefficients in the set $\{0, 1\}$. First, observe that the equation is not identically 0 because the coefficient of the term of degree 0 is not 0 (as the first letter of $\hat{w}$ must be $b$ since $a$ is not ambiguous). Second, every coefficient in the equation is in the set $\{-2, -1, 0, 1, 2\}$, and a classical result shows that if $\frac{p}{q}$ is a solution of a polynomial equation with $p$ and $q$ mutually prime, then $p$ divides the coefficient of degree 0, and $q$ divides the coefficient of highest degree. Therefore, no rational number in the interval $[\frac{1}{2}, 1]$ can be a solution. This shows that $n \neq m$ implies $S_n \neq S_m$, and thus the automaton $A$ cannot have finitely many states.

We note that cut-point languages are not stable under arbitrarily small perturbations of the transition weights, nor of the value of the cut-point. Consider the quantitative languages $L_1, L_2$ from the proof of Theorem 3.1. If for instance a limit-average automaton $A$ assigns weight $1 + \epsilon$ to the $a$’s and 0 to the $b$’s, its cut-point language $L_A^{\geq 1}$ is clearly different from $L_1^{\geq 1}$, no matter the value of $\epsilon > 0$. The same holds with respect to $L_2$ if $A$ is interpreted as a discounted-sum automaton.

In the theory of probabilistic automata, where finite words are assigned a probability of acceptance, the cut-point languages may also be non-regular. Therefore, one considers the special case where the cut-point is isolated, and shows that the cut-point languages are then regular [Rab63].

A number $\eta$ is an isolated cut-point of a quantitative language $L$ if there exists $\epsilon > 0$ such that

$$|L(w) - \eta| > \epsilon \text{ for all } w \in \Sigma^\omega.$$ We argue that isolated cut-point languages are robust, in that they remain unchanged under small perturbations of the transition weights. This follows from a more general result about the robustness of weighted automata.
A class of weighted automata is robust if a small (syntactical) perturbation in the weights of an automaton induces only a small (semantical) perturbation in the values of the words in the quantitative language of the automaton, and the semantical perturbation tends to 0 when the syntactical perturbation tends to 0. To formally define robustness, we need \( \epsilon \)-approximations of automata, and distance between quantitative languages.

Let \( A = (Q, q_I, \Sigma, \delta, \gamma) \) be a (nondeterministic) weighted automaton, and let \( \epsilon \in \mathbb{R}_{\geq 0} \). We say that a weighted automaton \( B = (Q', q'_I, \Sigma, \delta', \gamma') \) is an \( \epsilon \)-approximation of \( A \) if

- \( Q' = Q, q'_I = q_I, \delta' = \delta \), and
- \( |\gamma'(q, \sigma, q') - \gamma(q, \sigma, q')| \leq \epsilon \) for all \( (q, \sigma, q') \in \delta \).

The sup-distance between two quantitative languages \( L_1, L_2 : \Sigma^\omega \rightarrow \mathbb{R} \) is defined by

\[
D_{\sup}(L_1, L_2) = \sup_{w \in \Sigma^\omega} |L_1(w) - L_2(w)|.
\]

We say that a class \( C \) of weighted automata is uniformly robust if for all \( \eta \in \mathbb{R}_{>0} \), there exists \( \epsilon \in \mathbb{R}_{>0} \) such that for all automata \( A, B \in C \) such that \( B \) is an \( \epsilon \)-approximation of \( A \), we have \( D_{\sup}(L_A, L_B) \leq \eta \). Note that uniform robustness implies a weaker notion of robustness where a class \( C \) of weighted automata is called robust if for all automata \( A \in C \) and for all \( \eta \in \mathbb{R}_{>0} \), there exists \( \epsilon \in \mathbb{R}_{>0} \) such that for all \( \epsilon \)-approximations \( B \) of \( A \) (with \( B \in C \)), we have \( D_{\sup}(L_A, L_B) \leq \eta \) (here the value of \( \epsilon \) can depend for instance on the weights of the automaton \( A \)).

**Theorem 3.2.** The classes of (non)deterministic \( \text{Sup} \)-, \( \text{LimSup} \)-, \( \text{LimInf} \)-, \( \text{LimAvg} \)- and \( \text{Disc} \)-automata are uniformly robust.

**Proof.** Let \( A, B \) be two weighted automata with \( B \) an \( \epsilon \)-approximation of \( A \). It is easy to see that for \( \text{Sup} \)-, \( \text{LimSup} \)-, \( \text{LimInf} \)- and \( \text{LimAvg} \)-automata, the value of a run \( r \) of \( B \) differs by at most \( \epsilon \) from the value of the same run in \( A \). Therefore, \( D_{\sup}(L_A, L_B) \leq \epsilon \) and we can take \( \epsilon = \eta \). For \( \text{Disc} \)-automata, the value of a run of \( B \) differs by at most \( \frac{\epsilon}{1 - \lambda} \) from the value of the same run in \( A \), where \( \lambda \) is the discount factor. Therefore, we can take \( \epsilon = \eta (1 - \lambda) \).

As a corollary of Theorem 3.2, for an isolated cut-point \( \eta \), the cut-point language \( L^{\geq \eta} \) remains unchanged under small perturbations of the weights.

**Corollary 3.3.** Let \( L_A \) be the quantitative language defined by a weighted automaton \( A \), and let \( \eta \) be an isolated cut-point of \( L_A \). There exists a rational \( \epsilon > 0 \) such that for all \( \epsilon \)-approximations \( B \) of \( A \), we have \( L_A^{\geq \eta} = L_B^{\geq \eta} \) (where \( L_B \) is the quantitative language defined by \( B \)).

Now, we show that the isolated cut-point languages of deterministic discounted-sum and limit-average automata are \( \omega \)-regular. For nondeterministic automata, the same property holds in the discounted-sum case, but the question is open for limit-average.

**Theorem 3.4.** Let \( L \) be the quantitative language defined by a \( \text{Disc} \)-automaton. If \( \eta \) is an isolated cut-point of \( L \), then the cut-point language \( L^{\geq \eta} \) is \( \omega \)-regular.

**Proof.** Let \( \lambda \) be the discount factor of the \( \text{Disc} \)-automaton \( A \) that defines \( L \). Since \( \eta \) is an isolated cut-point of \( L \), let \( \epsilon > 0 \) such that \( |L(w) - \eta| > \epsilon \) for all \( w \in \Sigma^\omega \). Let \( n \in \mathbb{N} \) such that \( u_n = \frac{V \lambda^n}{1 - \lambda} < \epsilon \) where \( V = \max_{(q, \sigma, q') \in \delta_A}|\gamma(q, \sigma, q')| \) is the largest weight in \( A \). Note that \( u_n \) is a bound on the difference between the \( \lambda \)-discounted sum of the weights in any infinite run \( \hat{r} \) of \( A \) and the \( \lambda \)-discounted sum of the weights in the prefix of length \( n \) of \( \hat{r} \), and \( u_n \rightarrow 0 \) when \( n \rightarrow \infty \).
Consider an arbitrary run \( r \) in \( A \) of length \( n \), and let \( \gamma(r) \) be the \( \lambda \)-discounted sum of the weights along \( r \). Then, it should be clear that \( \gamma(r) \notin [\eta - \epsilon + u_n, \eta + \epsilon - u_n] \), because otherwise, the value of any (infinite) continuation of \( r \) would lie in the interval \([\eta - \epsilon, \eta + \epsilon]\), which would be a contradiction to the fact that \( \eta \) is an isolated cut-point of \( L \). Moreover, if \( \gamma(r) \leq \eta - \epsilon + u_n \), then any (infinite) continuation of \( r \) has value less than \( \eta - \epsilon + 2u_n < \eta + \epsilon \), and therefore less than \( \eta \), while if \( \gamma(r) \geq \eta + \epsilon - u_n \), then any (infinite) continuation of \( r \) has value greater than \( \eta \). Therefore, the cut-point language \( L^{2\eta} \) can be defined by the unfolding up to length \( n \) of the Disc-automaton that defines \( L \), in which the states that are reached via a path with value at least \( \eta + \epsilon - u_n \) are declared to be accepting (for Büchi condition), and have a self-loop on \( \Sigma \).

**Theorem 3.5.** Let \( L \) be the quantitative language defined by a deterministic \( \text{LimAvg} \)-automaton. If \( \eta \) is an isolated cut-point of \( L \), then the cut-point language \( L^{2\eta} \) is \( \omega \)-regular.

**Proof.** Let \( A \) be a deterministic \( \text{LimAvg} \)-automaton, defining the language \( L \). Consider the SCC-decomposition \( C_1, C_2, \ldots, C_k \) of the underlying graph of \( A \). For each \( 1 \leq i \leq k \), let \( m_i \) and \( M_i \) be the minimal and maximal average weight of a cycle in \( C_i \) (those values can be computed with Karp’s algorithm [Kar78]). It is easy to see that for every \( 1 \leq i \leq k \), for every \( v \in [m_i, M_i] \), there exists a word \( w \in \Sigma^\omega \) such that \( L(w) = v \). Therefore, since \( \eta \) is an isolated cut-point of \( L \), we have \( \eta \notin [m_i, M_i] \) for all \( 1 \leq i \leq k \). A deterministic Büchi automaton (DBW) for \( L^{2\eta} \) is obtained from \( A \) by declaring to be accepting all states \( q \) of \( A \) such that \( q \in C_i \) and \( m_i > \eta \). \( \square \)

3.2. **Boolean weights.** We consider weighted automata with boolean set of weights, i.e. all transitions have weight 0 or 1. The aim is to have a boolean counterpart to limit-average and discounted-sum automata, and compare the expressive power. We show that the restriction does not change the class of quantitative languages definable by limit-average automata, but does reduce the expressive power of discounted-sum automata.

**Theorem 3.6.** The class of nondeterministic (resp., deterministic) \( \text{LimAvg} \)-automata with rational weights in \([0, 1]\) is reducible to the class of nondeterministic (resp., deterministic) \( \text{LimAvg} \)-automata with weights 0 and 1 only.

**Proof.** Given a NLAVG \( A = (Q, q_I, \Sigma, \delta, \gamma) \) with weights in \([0, 1]\), we construct a NLAVG \( B \) with weights in \( \{0, 1\} \) such that \( L_A = L_B \).

First, let \( W = \{\gamma(q, \sigma, q') \mid (q, \sigma, q') \in \delta\} \) be the set of weights that occur in \( A \), and let \( n_A \) be the smallest integer \( n \) such that for all \( v \in W \), there exists \( p \in \mathbb{N} \) such that \( v = \frac{p}{n} \) (i.e., \( \frac{1}{n_A} \) is the greatest common divisor of the weights of \( A \)). We define \( B = (Q', q'_I, \Sigma, \delta', \gamma') \) as follows:

- \( Q' = Q \times [n_A] \) (where \([n_A]\) denotes the set \(\{0, 1, \ldots, n_A - 1\}\)). Intuitively, when we reach a state \((q, i)\) in \( B \), it means that the state \( q \) was reachable in \( A \) and that the sum of the weights to reach \( q \) is of the form \( k + \frac{1}{n_A} \) for some integer \( k \). In \( B \) however, the sum of the weights to reach \((q, i)\) will then be \( k \), and we store in the discrete state the information that the remainder weight is \( \frac{1}{n_A} \). Whenever this remainder exceeds 1, we introduce a weight 1 and decrement the remainder.
- \( q'_I = (q_I, 0) \);
- for each transition \((q, \sigma, q') \in \delta \) and each value \( i \in [n_A] \), the following transitions are in \( \delta' \) (where \( v = \gamma(q, \sigma, q') \)):
Moreover, if the average weight of a prefix of length \( n \) the word \( \text{Strictly smaller than} \ L \) A \text{implement and sum. We say that a class} C \text{property of} C \text{largest weight in} A \text{such that} \ L \cdot \ A \text{construct the automaton} A \text{present in this paper are constructive: when} a \text{from the initial state over} C \text{states. Analogously, the value of the corresponding run in} A \text{automaton} A \text{with weight} 1 \text{(as this would imply that} L_A(ab^\omega) \geq 1 \text{). Now, the maximal value that} L_A \text{can assign to the word} a^\omega \text{is} \lambda + \lambda^2 + \lambda^3 + \cdots = \frac{\lambda}{1-\lambda} \text{which is strictly smaller than} L_\lambda(a^\omega) = \frac{1+\lambda}{2(1-\lambda)}. \text{This shows that} A \text{cannot exist.} \]

\[ \text{Theorem 3.7. The class of deterministic Disc-automata with rational weights in} [0,1] \text{is not reducible to the class of (even nondeterministic) Disc-automata with weights 0 and 1 only.} \]

\[ \text{Proof. Given a discount factor} 0 < \lambda < 1, \text{consider the DDisc over} \Sigma = \{a,b\} \text{that consists of a single state with a self-loop over} a \text{with weight} \frac{1+\lambda}{2} \text{and a self-loop over} b \text{with weight} 0. \text{Let} L_1 \text{be the quantitative language defined by this automaton. Towards a contradiction, assume that this language is defined by a NDisc} A \text{with weights in} \{0,1\}. \text{First, consider the word} ab^\omega \text{whose value in} L_A \text{is} \frac{1+\lambda}{2} < 1 \text{. This entails that} A \text{cannot have a transition from the initial state over} a \text{with weight 1 (as this would imply that} L_A(ab^\omega) \geq 1 \text{). Now, the maximal value that} L_A \text{can assign to the word} a^\omega \text{is} \lambda + \lambda^2 + \lambda^3 + \cdots = \frac{\lambda}{1-\lambda} \text{which is strictly smaller than} L_\lambda(a^\omega) = \frac{1+\lambda}{2(1-\lambda)}. \text{This shows that} A \text{cannot exist.} \]

4. Closure Properties

We study the closure properties of weighted automata with respect to max, min, complement and sum. We say that a class \( C \) of weighted automata is \textit{closed} under a binary operator \( \text{op}(\cdot, \cdot) \) (resp. a unary operator \( \text{op'}(\cdot) \)) if for all \( A_1, A_2 \in C \), there exists \( A_{12} \in C \) such that \( L_{A_{12}} = \text{op}(L_{A_1}, L_{A_2}) \) (resp. \( L_{A_{12}} = \text{op'}(L_{A_1}) \)). All closure properties that we present in this paper are constructive: when \( C \) is closed under an operator, we can always construct the automaton \( A_{12} \in C \) given \( A_1, A_2 \in C \). We say that the \textit{cost} of the closure property of \( C \) under a binary operator \( \text{op} \) is at most \( O(f(n_1, m_1, n_2, m_2)) \) if for all automata \( A_1, A_2 \in C \) with \( n_i \) states and \( m_i \) transitions (for \( i = 1, 2 \) respectively), the constructed automaton \( A_{12} \in C \) such that \( L_{A_{12}} = \text{op}(L_{A_1}, L_{A_2}) \) has at most \( O(f(n_1, m_1, n_2, m_2)) \) many states. Analogously, the \textit{cost} of the closure property of \( C \) under a unary operator \( \text{op'} \) is at most \( O(f(n, m)) \) if for all automata \( A_1 \in C \) with \( n \) states and \( m \) transitions, the constructed automaton \( A_{12} \in C \) such that \( L_{A_{12}} = \text{op'}(L_{A_1}) \) has at most \( O(f(n, m)) \) many states. For all reductions presented, the size of the largest weight in \( A_{12} \) is linear in the size \( p \) of the largest weight in \( A_1, A_2 \) (however, the time needed to compute the weights is quadratic in \( p \), as we need addition, multiplication, or comparison, which are quadratic in \( p \)).

Notice that every class of weighted automata is closed under shift by \( c \) and under scale by \( |c| \) for all \( c \in \mathbb{Q} \). For \textbf{Sum}-automata and discounted-sum automata, we can define the shift by \( c \) by making a copy of the initial states and adding \( c \) to the weights of all its outgoing transitions. For the other automata, it suffices to add \( c \) to (resp. multiply by \( |c| \)) all weights of an automaton to obtain the automaton for the shift by \( c \) (resp. scale by \( |c| \)) of
its language. Therefore, all closure properties also hold if the complement of a quantitative language $L$ was defined as $k - L$ for any constant $k$.

Our purpose is the study of quantitative languages over infinite words. For the sake of completeness we first give an overview of the closure properties for finite words. Table 1(a) summarizes the closure properties for finite words, and Table 1(b) for infinite words.

4.1. Closure properties for finite words. For finite words, we consider closure under max, min, complement, and sum for Max-, Last- and Sum-automata.

**Theorem 4.1.** Deterministic Max- and Last-automata are closed under max, with cost $O(n_1 \cdot n_2)$. Nondeterministic Max-, Last- and Sum-automata are closed under max, with cost $O(n_1 + n_2)$. Deterministic Sum-automata are not closed under max.

**Proof.** For the nondeterministic automata, the result follows from the fact that the max operator can be obtained by an initial nondeterministic choice between two quantitative automata. For deterministic Max- and Last-automata, the result is obtained using a standard synchronized product construction, where the weight of a transition in the product is the maximum of the corresponding transition weights in the two automata. Finally, deterministic Sum-automata are not closed under the max operator because the language over $\Sigma = \{a, b\}$ that assigns to each finite word $w \in \Sigma^+$ the number $\max\{L_a(w), L_b(w)\}$ where $L_a(w)$ is the number of occurrences of $a$ in $w$ (for $\sigma = a, b$) is definable by the max of two deterministic-Sum languages, but not by a deterministic Sum-automaton (Theorem 2 in [CDH08]).

**Theorem 4.2.** Deterministic and nondeterministic Max-automata are closed under min, with cost $O(n_1 \cdot m_1 \cdot n_2 \cdot m_2)$. Deterministic and nondeterministic Last-automata are closed under min, with cost $O(n_1 \cdot n_2)$. Deterministic and nondeterministic Sum-automata are not closed under min.

**Proof.** Given two Last-automata $A_1$ and $A_2$ (over the same alphabet), we use the classical synchronized product $A_{12} = A_1 \times A_2$, where the weight of a transition in $A_{12}$ is the minimum of the corresponding transition weights in $A_1$ and $A_2$. It is easy to see that $L_{A_{12}} = \min(L_{A_1}, L_{A_2})$. If $A_1$ and $A_2$ are deterministic, then so is $A_{12}$.

The construction for Max-automata is the same as for Sup-automata over infinite words given in the proof of Theorem 1.7.

Finally, for Sum-automata, consider the language $L_m$ over $\Sigma = \{a, b\}$ that assigns to each finite word $w \in \Sigma^+$ the value $\min\{L_a(w), L_b(w)\}$ where $L_a(w)$ is the number of occurrences of $a$ in $w$ (for $\sigma = a, b$). We claim that $L_m$ is not definable by a nondeterministic Sum-automaton. Indeed, assume that the Sum-automaton $A$ with state space $Q$ defines $L_m$. First, the sum of weights in every reachable cycle of $A$ over $a$’s must be at most 0. Otherwise, we can reach the cycle with a finite word $w_1$ and obtain an arbitrarily large value for the word $w_1a^i$ for $i$ sufficiently large, while for any such $i$ the value of $w_1a^i$ is the number of $b$’s in $w_1$ which is independent of $i$. Analogously, the sum of weights in every reachable cycle of $A$ over $b$’s must be at most 0. Now, let $\beta = \max_{e \in E}|\gamma(e)|$ be the maximal weight in $A$, and consider the word $w = a^n b^n$ for $n > 2\beta \cdot |Q|$. Every run of $A$ over $a^n$ (or over $b^n$) can be decomposed in possibly nested cycles (since $A$ is nondeterministic) and a remaining non-cyclic path of length at most $|Q|$. Hence, the value of any run over $w$ is at most $2\beta \cdot |Q|$. However, the value of $w$ should be $n$, thus $A$ cannot exist.
**Theorem 4.3.** Deterministic Last- and Sum-automata are closed under complement, with cost $O(n)$. Nondeterministic Last-automata are closed under complement, with cost $O(2^n)$. Nondeterministic Sum automata, and both deterministic and nondeterministic Max-automata are not closed under complement.

**Proof.** To define the complement of the language of a deterministic Sum- (or Last-) automaton, it suffices to multiply all the weights by $-1$, and then shift the language by 1. For the class of nondeterministic Last-automata, the result follows from the fact that it is reducible to its deterministic counterpart.

The negative result for Max-automata follows from an analogous in the boolean case (consider the language $L$ over $\{a, b\}$ such that $L(a^i) = 0$ for all $i \geq 1$, and $L(w) = 1$ for all words containing the letter $b$). Finally, according to the proof of Theorem 4.1, the language $\min(L_a, L_b)$ where $L_\sigma(w)$ is the number of occurrences of $\sigma$ in $w$ (for $\sigma = a, b$) is not definable by a nondeterministic Sum-automaton. Since $\min(L_a, L_b) = 1 - \max(1 - L_a, 1 - L_b)$ and (i) $1 - L_a$ and $1 - L_b$ are definable by Sum-automata, and (ii) nondeterministic Sum-automata are closed under max (Theorem 4.1), the language $\max(1 - L_a, 1 - L_b)$ is definable by a nondeterministic Sum-automaton, but not its complement and the result follows.

**Theorem 4.4.** Every class of weighted automata over finite words is closed under sum. The cost is $O(n_1 \cdot n_2)$ for Last- and Sum-automata, and $O(n_1 \cdot m_1 \cdot n_2 \cdot m_2)$ for Max-automata.

**Proof.** It is easy to see that the synchronized product of two Last-automata (resp. Sum-automata) defines the sum of their languages if the weight of a joint transition is defined as the sum of the weights of the corresponding transitions in the two Last-automata (resp. Sum-automata).

We give the construction for two Max-automata $A_1 = \langle Q_1, q_1^1, \Sigma, \delta_1, \gamma_1 \rangle$ and $A_2 = \langle Q_2, q_2^1, \Sigma, \delta_2, \gamma_2 \rangle$. We construct a Max-automaton $A_{12} = \langle Q, q_1, \Sigma, \delta, \gamma \rangle$ such that $L_{A_{12}} = \max(L_{A_1} + L_{A_2})$. Let $V_i = \{\gamma_i(e) \mid e \in \delta_i\}$ be the set of weights that appear in $A_i$ (for $i = 1, 2$), and define:

- $Q = Q_1 \times V_1 \times Q_2 \times V_2$. Intuitively, we remember in a state $(q_1, v_1, q_2, v_2)$ the largest weights $v_1, v_2$ seen so far in the corresponding runs of $A_1$ and $A_2$;
- $q_t = (q_t^1, v_t^1, q_t^2, v_t^2)$ where $v_t^i$ is the minimal weight in $V_i$ (for $i = 1, 2$);
- For each $\sigma \in \Sigma$, the set $\delta$ contains all the triples $((q_1, v_1, q_2, v_2), \sigma, (q'_1, v'_1, q'_2, v'_2))$ such that $v_i \in V_i$, $(q_i, \sigma, q'_i) \in \delta_i$, and $v'_i = \max\{v_i, \gamma(q_i, \sigma, q'_i)\}$, for $i = 1, 2$;
- $\gamma$ is defined by $\gamma((q_1, v_1, q_2, v_2), \sigma, (q'_1, v'_1, q'_2, v'_2)) = v'_1 + v'_2$

for each $((q_1, v_1, q_2, v_2), \sigma, (q'_1, v'_1, q'_2, v'_2)) \in \delta$.

If $A_1$ and $A_2$ are deterministic, then $A_{12}$ is deterministic. The result for deterministic Max-automata follows.

### 4.2. Closure under max for infinite words

The maximum of two quantitative languages defined by nondeterministic automata can be obtained by an initial nondeterministic choice between the two automata. This observation was also made in [DRA07] for discounted-sum automata. For deterministic automata, a synchronized product can be used for $\text{Sup}$ and $\text{LimSup}$, while for $\text{LimInf}$ we use the fact that $\text{NLInf}$ is determinizable with an exponential blow-up [CDH08].
Theorem 4.5. The nondeterministic $\text{Sup}$-, $\text{LimSup}$-, $\text{LimInf}$-, $\text{LimAvg}$- and $\text{Disc}$-automata are closed under max, with cost $O(n_1 + n_2)$, the deterministic $\text{Sup}$- and $\text{LimSup}$-automata with cost $O(n_1 \cdot n_2)$, the deterministic $\text{LimInf}$-automata with cost $O((m_1 + m_2)^{n_1+n_2})$.

Sketch. For all the nondeterministic quantitative automata, the result follows from the fact that the max operator can be achieved with an initial nondeterministic choice between two weighted automata. For $\text{DLInf}$, the result follows from the reducibility of $\text{NLinf}$ to $\text{DLInf}$ with an exponential blow-up [CDH08]. We now prove that $\text{DLsup}$ and $\text{DSup}$ are closed under max with cost $O(n_1 \cdot n_2)$. Given two $\text{DLsup}$ (or $\text{DSup}$) $A_1$ and $A_2$ over the same alphabet, we construct the usual synchronized product $A_{12} = A_1 \times A_2$, where the weight of a transition in $A_{12}$ is the maximum of the corresponding transition weights in $A_1$ and $A_2$. It is easy to see that $L_{A_{12}} = \max(L_{A_1}, L_{A_2})$ in both cases.

Theorem 4.6. The deterministic $\text{LimAvg}$- and $\text{Disc}$-automata are not closed under max.

Proof. The fact that $\text{DDisc}$ is not closed under max follows from the proof of Theorem 16 in [CDH08], where it is shown that the quantitative language $\max(L_1, L_2)$ cannot be defined by a $\text{DDisc}$, where $L_1$ (resp. $L_2$) is the language defined by the $\text{DDisc}$ that assigns weight 1 (resp. 0) to $a$'s and weight 0 (resp. 1) to $b$'s.

We now show that $\text{DLavg}$ is not closed under max. Consider the alphabet $\Sigma = \{a, b\}$ and the quantitative languages $L_a$ and $L_b$ that assign the value of long-run average number of $a$'s and $b$'s, respectively. There exists $\text{DLavg}$ for $L_a$ and $L_b$. We show that $L_m = \max(L_a, L_b)$ cannot be expressed by a $\text{DLavg}$. By contradiction, assume that $A$ is a $\text{DLavg}$ with set of states $Q$ that defines $L_m$. Consider any reachable cycle $C$ over $a$'s in $A$. The sum of the weights of the cycle must be its length $|C|$, as if we consider the word $w^* = w_C \cdot (a^{|C|})^\omega$ where $w_C$ is a finite word whose run reaches $C$, the value of $w^*$ in $L_m$ is 1. It follows that the sum of the weights of the cycle $C$ must be at most $|C|$. Hence, the sum of the weights of all the reachable cycles $C$ over $a$'s in $A$ is $|C|$.

Consider the infinite word $w_\infty = (a^{|Q|} \cdot b^{|Q|})^\omega$, and let $w_j = (a^{|Q|} \cdot b^{|Q|})^j$. Since $L_m(w_\infty) = \frac{2}{3}$, the run of $A$ over $w_\infty$ has value $\frac{2}{3}$. It follows that for all $\varepsilon > 0$, there is an integer $j_\varepsilon$, such that for all $j \geq j_\varepsilon$, we have
\[
\frac{\gamma(w_j)}{|w_j|} \geq \frac{2}{3} - \varepsilon
\]
where $\gamma(w_j)$ is the sum of the weights of the run of $A$ over $w_j$. Consider a word $\hat{w}_\infty$ constructed as follows. We start with the empty word $\hat{w}_0$ and the initial state $q_0$ of $A$, and for all $j \geq 0$, we construct $(\hat{w}_{j+1}, q_{j+1})$ from $(\hat{w}_j, q_j)$ as follows: the state $q_{j+1}$ is the last state of the run of $A$ from $q_j$ over $a^{|Q|} \cdot b^{|Q|}$. This run has to contain a cycle $C_{j+1}$ over $a$'s. We set $\hat{w}_{j+1} = \hat{w}_j \cdot a^{|Q|} \cdot b^{|Q|}$. Observe that for all $j \geq 1$, the run of $A$ over $w_\infty$ in the segment between $w_j$ and $w_{j+1}$ is identical to the run from $q_j$ to $q_{j+1}$ up to the repetition of the cycle $C_{j+1}$ once more. The word $\hat{w}_\infty$ is the limit of this construction ($\hat{w}_j$ is a prefix of $\hat{w}_\infty$ for all $j \geq 0$). Let $\alpha_j = \sum_{i=1}^j |C_i|$. Since $1 \leq |C_i| \leq |Q|$ we have $j \geq \alpha_j \leq j \cdot |Q|$. Hence we have the following equality: $\frac{\gamma(\hat{w}_j)}{|w_j|} = \frac{\gamma(w_j) + \alpha_j}{|w_j| + \alpha_j}$. Hence for all $\varepsilon > 0$, there exists $j_\varepsilon$ such...
that for all $j \geq j_\varepsilon$ we have
\[
\frac{\gamma(\hat w_j)}{|\hat w_j|} \geq \frac{2}{3} \cdot \frac{|w_j| - \varepsilon \cdot |w_j| + \alpha_j}{|w_j| + \alpha_j} \\
\geq \frac{2}{3} - \varepsilon + \frac{1}{3} \cdot \frac{\alpha_j}{|w_j| + \alpha_j} \\
\geq \frac{2}{3} - \varepsilon + \frac{1}{3} \cdot \frac{j \cdot (|Q| + |Q|)}{1} \\
\geq \frac{2}{3} - \varepsilon + \frac{1}{12|Q|}.
\]

This shows that $\liminf_{j \to \infty} \frac{\gamma(\hat w_j)}{|w_j|} \geq \frac{2}{3} + \frac{1}{12|Q|}$ and thus we have $L_A(\hat w_\infty) \geq \frac{2}{3} + \frac{1}{12|Q|}$. Since $1 \leq |C_i| \leq |Q|$ for all $i \geq 1$, we have $L_m(\hat w_\infty) \leq \frac{2}{3}$ which is a contradiction. \qed

4.3. Closure under $\min$ for infinite words. The positive results about closure properties under $\min$ for quantitative languages generalize the closure properties of boolean languages under intersection. The constructions are straightforward extensions of the standard constructions for finite, Büchi, and coBüchi automata (see e.g. [Var96]).

Theorem 4.7. The (non)deterministic $\sup$-automata are closed under $\min$, with cost $O(n_1 \cdot m_1 \cdot m_2)$.

Proof. The construction in the proof of Theorem 4.4 can be adapted by defining the weight $\gamma((q_1, v_1, q_2, v_2), \sigma, (q'_1, v'_1, q'_2, v'_2))$ as $\min\{v'_1, v'_2\}$ for each $(q_1, v_1, q_2, v_2), \sigma, (q'_1, v'_1, q'_2, v'_2) \in \delta$.

\qed

Theorem 4.8. The deterministic $\limsup$-automata are closed under $\min$ with cost $O(n_1 \cdot m_2 \cdot 2^{m_1 + m_2})$.

Proof. Let $A_1 = \langle Q_1, q_1^1, \Sigma, \delta_1, \gamma_1 \rangle$ and $A_2 = \langle Q_2, q_2^1, \Sigma, \delta_2, \gamma_2 \rangle$ be two DLSUP. We construct a DLSUP $A = \langle Q, q_i, \Sigma, \delta, \gamma \rangle$ such that $L_A = \min\{L_{A_1}, L_{A_2}\}$. Let $V_i = \gamma_i(e) \mid e \in \delta_i$ be the set of weights that occur in $A_i$ (for $i = 1, 2$). For each weight $v \in V_1 \cup V_2 = \{v_1, \ldots, v_n\}$, we construct a DBW $A_1 v_2$ that consists of a copy of $A_1$ and a copy of $A_2$. We switch from one copy to the other whenever an edge with weight at least $v$ is crossed. All such switching edges are accepting in $A_1 v_2$ (i.e., they have weight 1 while all other edges have weight 0). The automaton $A$ then consists of the synchronized product of these DBW, where the weight of a joint edge is the largest weight $v$ for which the underlying edge in $A_1 v_2$ is accepting. Formally, let
- $Q = Q_1 \times Q_2 \times \{1, 2\}^m$ where $m = |V_1 \cup V_2|$ (and assume $V_1 \cup V_2 = \{v_1, \ldots, v_m\}$);
- $q_i = (q_1^i, q_2^i, b_1, \ldots, b_m)$ where $b_i = 1$ for all $1 \leq i \leq m$;
- $\delta$ contains all the triples $(q_1, q_2, b_1, \ldots, b_m), \sigma, (q'_1, q'_2, b'_1, \ldots, b'_m))$ such that $\sigma \in \Sigma$ and
- $(q_i, \sigma, q'_i) \in \delta_i$ for $i = 1, 2$;
- for all $1 \leq j \leq m$, we have $b'_j = 3 - b_j$ if $\gamma(b_j(q_0, \sigma, q'_b) \geq v_j)$, and $b'_j = b_j$ otherwise.
- $\gamma$ assigns to each transition $(q_1, q_2, b_1, \ldots, b_m), \sigma, (q'_1, q'_2, b'_1, \ldots, b'_m)) \in \delta$ the weight $v = \max(\{v_{min} \cup \{v_j \mid b_j \neq b'_j\}\}$ where $v_{min}$ is the minimal weight in $V_1 \cup V_2$. \qed
Theorem 4.9. The (non)deterministic LimInf-automata are closed under min with cost $O(n_1 \cdot n_2)$, and the nondeterministic LimSup-automata with cost $O(n_1 \cdot n_2 \cdot (m_1 + m_2))$.

Proof. Let $A_1 = \langle Q_1, q_1^1, \Sigma, \delta_1, \gamma_1 \rangle$ and $A_2 = \langle Q_2, q_2^1, \Sigma, \delta_2, \gamma_2 \rangle$ be two NLSup. We construct a NLSup $A = \langle Q, q_1, \Sigma, \delta, \gamma \rangle$ such that $L_A = \min \{ L_{A_1}, L_{A_2} \}$. Let $V_i = \{ \gamma_i(e) \mid e \in \delta_i \}$ be the set of weights that appear in $A_i$ (for $i = 1, 2$). Let $V_1 \cup V_2 = \{ v_1, \ldots, v_n \}$ and define

- $Q = \{ q_I \} \cup Q_1 \times Q_2 \times \{ 1, 2 \} \times (V_1 \cup V_2)$ (where $q_I \notin Q_1 \cup Q_2$ is a new state). Initially, a guess is made of the value $v$ of the input word. Then, we check that both $A_1$ and $A_2$ visit a weight at least $v$ infinitely often. In a state $(q_1, q_2, j, v)$ of $A$, the guess is stored in $v$ (and will never change along a run) and the value of the index $j$ is toggled to $3 - j$ as soon as $A_j$ does visit a weight at least $v$;

- For each $\sigma \in \Sigma$, the set $\delta$ contains all the triples
  - $(q_1, \sigma, (q_1, q_2, 1, v))$ such that $v \in V_1 \cup V_2$ and for all $i \in \{ 1, 2 \}$, we have $(q_i', \sigma, q_i) \in \delta_i$.
  - $(\langle q_1, q_2, j, v \rangle, \sigma, \langle q_1', q_2', j', v' \rangle)$ such that $v' = v$, $(q_i', \sigma, q_i) \in \delta_i$ ($i = 1, 2$), and $j' = 3 - j$ if $\gamma_j(q_j, \sigma, q_j') \geq v$, and $j' = j$ otherwise.

- $\gamma$ is defined by $\gamma(q_1, \sigma, (q_1, q_2, 1, v)) = 0$ and $\gamma((q_1, q_2, j, v), \sigma, (q_1', q_2', j', v'))$ is $v$ if $j \neq j'$ and $v_{\min}$ otherwise, where $v_{\min}$ is the minimal weight in $V_1 \cup V_2$.

For the case of LimInf-automata $A_1, A_2$, we can use the synchronized product $A_{12} = A_1 \times A_2$, where the weight of a joint transition in $A_{12}$ is the minimum of the corresponding transition weights in $A_1$ and $A_2$. It is easy to see that $L_{A_{12}} = \min(L_{A_1}, L_{A_2})$ in both cases, and $A_{12}$ is deterministic when $A_1$ and $A_2$ are deterministic. This case is simpler also because for LimInf-automata, deterministic and nondeterministic automata have the same expressive power.

On the negative side, the (deterministic or not) limit-average and discounted-sum automata are not closed under min.

Theorem 4.10. The (non)deterministic LimAvg-automata are not closed under min.

Proof. Consider the alphabet $\Sigma = \{ a, b \}$, and consider the languages $L_a$ and $L_b$ that assign the long-run average number of $a$’s and $b$’s, respectively. Note that there exist DLAVG for the languages $L_a$ and $L_b$.

We show that there is no no NLAVG for the language $L_m = \min \{ L_a, L_b \}$. To obtain a contradiction, assume that there exists a NLAVG $A$ for $L_m$. We first claim that there must be either an $a$-cycle or a $b$-cycle $C$ that is reachable in $A$ such that the sum of the weights in $C$ is positive. Otherwise, if for all $a$-cycles and $b$-cycles we have that the sum of the weights is zero or negative, then we fool the automaton as follows. Let $\beta$ be the maximum of the absolute values of the weights in $A$, and let $\alpha = \lfloor \beta \rfloor$. Then consider the word $w = (a^{5 \cdot \lfloor |Q| \cdot \beta} \cdot b^{5 \cdot \lfloor |Q| \cdot \alpha})^\omega$. For a run $r$ of $A$ over $w$, the long-run average of the weights is bounded as follows:

$$\frac{4 \cdot \beta \cdot |Q|}{10 \cdot \alpha \cdot |Q|} \leq \frac{2}{5}.$$ 

The above bound is as follows: in the run over $a^{5 \cdot \lfloor |Q| \cdot \beta}$, there can be a prefix of size at most $|Q|$ with sum of weights at most $|Q| \cdot \beta$, and then there would be $a$-cycles, and then a trailing prefix of size at most $|Q|$ with sum of weights at most $|Q| \cdot \beta$. Similar argument holds for the segment of $b^{5 \cdot \lfloor |Q| \cdot \alpha}$. Hence $L_A(w) \leq \frac{2}{5}$, however, $L_m(w) = \frac{1}{2}$, i.e., we have a contradiction. W.l.o.g., we assume that there is an $a$-cycle $C$ such that the sum of weights of $C$ is positive. Then we present the following word $w$: a finite word $w_C$ to reach the cycle $C$, followed by
for $DLsup$ in [CDH08], there exists an infinite word $\hat{w}$ such that $L_{\lambda}$ be the $q$ and $\lambda$ is not null in (4.1).

The (non)deterministic $\omega$-automata are not closed under complement. The next result is a direct extension of the boolean case.

Finally, we show that discounted-sum automata are not closed under $\min$.

**Theorem 4.11.** The (non)deterministic $\text{Disc-automata}$ are not closed under $\min$.

**Proof.** Let $\lambda$ be a non-algebraic number in $]\frac{1}{2}, 1[.$ We consider the quantitative languages $L^\lambda_a$ and $L^\lambda_b$ that assign the $\lambda$-discounted sum of $a$'s and $b$'s, respectively. Formally, given a (finite or infinite) word $w = w_0 w_1 \cdots \in \Sigma^* \cup \Sigma^\omega$, let

$$v_a(w) = \sum_{i \mid w_i = a} \lambda^i \quad \text{and} \quad v_b(w) = \sum_{i \mid w_i = b} \lambda^i$$

be the $\lambda$-discounted sum of the $a$'s (resp. $b$'s) of $w$. Then, $L^\lambda_a(w) = v_a(w)$ and $L^\lambda_b(w) = v_b(w)$. These languages are definable by $\text{DDisc}$. We show that the language $L_m = \min(L^\lambda_a, L^\lambda_b)$ is not definable by a $\text{NDisc}$.

Assume towards contradiction that there is a $\text{NDisc} A$ for $L_m$. By Lemmas 2 and 3 in [CDH08], there exists an infinite word $\hat{w}$ such that $v_a(\hat{w}) = v_b(\hat{w})$.

Since $v_a(\hat{w}) + v_b(\hat{w}) = \frac{1}{1-\lambda}$, we have $L_m(\hat{w}) = \frac{1}{2(1-\lambda)}$ and this is the maximal value of a word in $L_m(\cdot)$.

The maximal value in the automaton $A$ can be obtained for a lasso-word of the form $w_1.(w_2)^\omega$ (where $w_1, w_2$ are finite words and $w_2$ is nonempty), as pure memoryless strategies exist in games over finite graphs with the objective to maximize the discounted sum of payoffs. Since the language of $A$ is $L_m$, the value of $w_1.(w_2)^\omega$ is $\frac{1}{2(1-\lambda)}$, and thus $v_a(w_1.(w_2)^\omega) = v_b(w_1.(w_2)^\omega)$ by a similar argument as above. This last condition can be written as

$$p_a(\lambda) + \frac{\lambda^{n_1} \cdot q_a(\lambda)}{1 - \lambda^{n_2}} = p_b(\lambda) + \frac{\lambda^{n_1} \cdot q_b(\lambda)}{1 - \lambda^{n_2}}$$

for some polynomials $p_a, p_b, q_a, q_b$ and integers $n_1 \geq 0$ and $n_2 > 0$, or more simply as

$$(1 - \lambda^{n_2}) \cdot p(\lambda) + \lambda^{n_1} \cdot q(\lambda) = 0$$

(4.1) for some polynomials $p$ of degree $n_1 - 1$ and $q$ of degree $n_2 - 1$, all of whose coefficients are either 1 or -1. Equation (4.1) is not identically zero as either (i) $n_1 = 0$ and it reduces to $q(\lambda) = 0$ or (ii) $n_1 > 0$ and then $p$ has degree at least 0 so that the term of degree zero is not null in (4.1).

Therefore, $\lambda$ must be algebraic, a contradiction. \hfill \Box

4.4. Closure under complement for infinite words. Most of the weighted automata are not closed under complement. The next result is a direct extension of the boolean case.

**Theorem 4.12.** The (non)deterministic $\text{Sup}$- and $\text{LimInf}$-automata, and the deterministic $\text{LimSup}$-automata are not closed under complement.

**Proof.** The result follows from a similar result for the boolean version of these classes. For $\text{DSup}$ and $\text{NSup}$, consider the language $L_1$ over $\Sigma = \{a, b\}$ such that $L_1(a^{\omega}) = 0$ and $L_1(w) = 1$ for all $w \neq a^{\omega}$. For $\text{DLinf}$ and $\text{NLinf}$, consider the language $L_2$ over $\Sigma = \{a, b\}$ such that $L_2(\Sigma^+.a^{\omega}) = 1$ and $L(w) = 0$ for all words $w$ containing infinitely many $b$'s, and for $\text{DLsup}$, consider $L_3$ the complement of $L_2$. \hfill \Box
The next theorem is a positive result of closure under complementation for NLsup. It reduces to the complementation of nondeterministic Büchi automata.

**Theorem 4.13.** The nondeterministic LimSup-automata are closed under complement, with cost \( O(m \cdot 2^{n \log n}) \).

*Proof.* Let \( A = (Q, q_0, \Sigma, \delta, \gamma) \) be a NLsup, and let \( V = \{ \gamma(e) \mid e \in \delta \} \) be the set of weights that appear in \( A \). For each \( v \in V \), it is easy to construct a NBW \( A_v \) whose (boolean) language is the set of words \( w \) such that \( L_A(w) \geq v \), by declaring to be accepting the edges with weight at least \( v \). We then construct for each \( v \in V \) a NBW \( A_v \) (with accepting edges) that accepts the (boolean) complement of the language accepted by \( A_v \). Finally, assuming that \( V = \{ v_1, \ldots, v_n \} \) with \( v_1 < v_2 < \cdots < v_n \), we construct the NLsup \( B_i \) for \( i = 2, \ldots, n \) where \( B_i \) is obtained from \( A_{v_i} \) by assigning weight \( 1 - v_{i-1} \) to each accepting edges, and \( 1 - v_n \) to all other edges. The complement of \( L_A \) is then \( \max \{ L_{B_2}, \ldots, L_{B_n} \} \) which is accepted by a NLsup by Theorem 4.5.

**Theorem 4.14.** The deterministic Disc-automata are closed under complement, with cost \( O(n) \).

*Sketch.* It suffices to replace each weight \( v \) of a DDisc by \( 1 - \lambda - v \) (where \( \lambda \) is the discount factor) to obtain the DDisc for the complement.

**Theorem 4.15.** The deterministic LimAvg-automata are not closed under complement.

*Proof.* Consider the DLavg \( A \) over alphabet \( \Sigma = \{ a, b \} \) (shown in Figure 3) that consists of a single self-loop state with weight 1 for \( a \) and 0 for \( b \). Notice that \( L_A(w.a^w) = 1 \) and \( L_A(w.b^w) = 0 \) for all \( w \in \Sigma^* \). To obtain a contradiction, assume that there exists a DLavg \( B \) whose language is \( L_B = 1 - L_A \). For all finite words \( w \in \Sigma^* \), let \( L_B^{\text{Avg}}(w) \) be the average weight of the unique (finite) run of \( B \) over \( w \).

Fix \( 0 < \epsilon < \frac{1}{2} \). For all finite words \( w \), there exists a number \( n_w \) such that the average number of \( a \)'s in \( w.b^{n_w} \) is at most \( \epsilon \), and there exists a number \( m_w \) such that \( L_B^{\text{Avg}}(w.a^{m_w}) \leq \epsilon \) (since \( L_B(w.a^w) = 0 \)). Hence, we can construct a word \( w = b^{n_1}a^{n_1}b^{n_2}a^{n_2} \ldots \) such that \( L_A(w) \leq \epsilon \) and \( L_B(w) \leq \epsilon \). Since \( L_B = 1 - L_A \), this implies that \( 1 \leq 2\epsilon \), a contradiction.

**Theorem 4.16.** The nondeterministic LimAvg- and Disc-automata are not closed under complement.

*Proof.* The fact that NLavg are not closed under complementation is as follows. Consider the quantitative language \( L^* = 1 - \max \{ L_a, L_b \} \) where \( L_a \) and \( L_b \) assign the long-run average number of \( a \)'s and \( b \)'s, respectively. Exactly the same argument as in the proof of Theorem 4.10 shows that \( L^* \) cannot be expressed as a NLavg, while the language \( \max \{ L_a, L_b \} \) can be expressed as NLavg by Theorem 4.5.

Figure 3: Deterministic Limit-average Automaton.
That NDISC are not closed under complement can be obtained as follows: given $0 < \lambda < 1$, consider the language $L^\lambda_a$ and $L^\lambda_b$ that assigns to words the $\lambda$-discounted sum of $a$’s and $b$’s, respectively. The language $L^\lambda_a$ and $L^\lambda_b$ can be expressed as DDISC, and the max of them can be defined by NDISC. Observe that $L^\lambda_a(w) + L^\lambda_b(w) = \frac{1}{1-\lambda}$ for all $w \in \Sigma^\omega$. Therefore, $\min\{L^\lambda_a, L^\lambda_b\} = \frac{1}{1-\lambda} - \max\{L^\lambda_a, L^\lambda_b\}$. Since NDISC is not closed under min (Theorem 4.11), we immediately obtain that NDISC are not closed under complementation. \qed

4.5. Closure under sum for infinite words. All weighted automata are closed under sum, except DLAVG and NLAVG.

Theorem 4.17. The (non)deterministic Sup-automata are closed under sum, with cost $O(n_1 \cdot m_1 \cdot n_2 \cdot m_2)$.

Proof. The construction is the same as for Max-automata over finite words given in the proof of Theorem 4.3 \qed

Theorem 4.18. The nondeterministic LimSup-automata are closed under sum, with cost $O(n_1 \cdot m_1 \cdot n_2 \cdot m_2)$.

Sketch. Given two NLsup $A_1$ and $A_2$, we construct a NLsup $A$ for the sum of their languages as follows. Initially, we make a guess of a pair $(v_1, v_2)$ of weights $(v_i$ in $A_i$ for $i = 1, 2$) and we branch to a copy of the synchronized product of $A_1$ and $A_2$. We attach a bit $b$ whose range is $\{1, 2\}$ to each state to remember that we expect $A_b$ to visit the guessed weight $v_b$. Whenever this occurs, the bit $b$ is set to $3 - b$, and the weight of the transition is $v_1 + v_2$. All other transitions (i.e. when $b$ is unchanged) have weight $\min\{v_1 + v_2 \mid v_1 \in V_1 \land v_2 \in V_2\}$. \qed

Theorem 4.19. The deterministic LimSup-automata are closed under sum, with cost $O(n_1 \cdot m_1 \cdot n_2 \cdot 2^{m_1 \cdot m_2})$.

Proof. Let $A_1 = \langle Q_1, q^1_1, \Sigma, \delta_1, \gamma_1 \rangle$ and $A_2 = \langle Q_2, q^2_1, \Sigma, \delta_2, \gamma_2 \rangle$ be two DLsup. We construct a DLsup $A = \langle Q, q^1_1, \Sigma, \delta, \gamma \rangle$ such that $L_A = L_{A_1} + L_{A_2}$. Let $V_i = \{\gamma_i(e) \mid e \in \delta_i\}$ be the set of weights that appear in $A_i$ (for $i = 1, 2$). The automaton $A$ implements the synchronized product of $A_1$ and $A_2$, and keeps one bit $b(v_1, v_2)$ for each pair $(v_1, v_2)$ of weights $v_1 \in V_1$ and $v_2 \in V_2$. For $i = 1, 2$, if $b(v_1, v_2) = i$, then $A_i$ is expected to cross a transition with weight $v_i$. Whenever this occurs, the bit is set to $3 - i$. The weight of a transition in $A$ is the largest value of $v_1 + v_2$ such that the corresponding bit $b(v_1, v_2)$ has changed in the transition. Formally, we define:

- $Q = Q_1 \times Q_2 \times [V_1 \times V_2 \rightarrow \{1, 2\}]$;
- $q_i = \langle q^i_1, q^i_2, b_i \rangle$ where $b_i(v_1, v_2) = 1$ for all $(v_1, v_2) \in V_1 \times V_2$;
- For each $\sigma \in \Sigma$, the set $\delta$ contains all the triples $((q_1, q_2, b), \sigma, (q'_1, q'_2, b'))$ such that $(q_i, \sigma, q'_i) \in \delta_i$ (i = 1, 2), and for all $(v_1, v_2) \in V_1 \times V_2$, we have $b'(v_1, v_2) = 3 - b(v_1, v_2)$ if $\gamma(\langle q_1, q_2, b \rangle, \sigma, (q'\_1, q'\_2, b')) = v_i$ for $i = b(v_1, v_2)$, and otherwise $b'(v_1, v_2) = b(v_1, v_2)$.
- $\gamma$ is defined by $\gamma((q_1, q_2, b), \sigma, (q'\_1, q'\_2, b')) = \max\{v_{\min} \cup \{v_1 + v_2 \mid b'(v_1, v_2) \neq b(v_1, v_2)\}\}$ where $v_{\min}$ is the minimal weight in $V_1 + V_2 = \{v_1 + v_2 \mid v_1 \in V_1 \land v_2 \in V_2\}$. \qed
Theorem 4.20. The (non)deterministic LimInf-automata are closed under sum with cost \(O(n_1 \cdot n_2 \cdot 2^{m_1+m_2})\).

Proof. Let \(A_1 = \langle Q_1, q_1^1, \Sigma, \delta_1, \gamma_1 \rangle\) and \(A_2 = \langle Q_2, q_2^2, \Sigma, \delta_2, \gamma_2 \rangle\) be two NLinf. We construct a NLinf \(A = \langle Q, q_1, \Sigma, \delta, \gamma \rangle\) such that \(L_A = L_{A_1} + L_{A_2}\). Let \(V_i = \{\gamma_i(e) \mid e \in \delta_i\}\) be the set of weights that appear in \(A_i\) (for \(i = 1, 2\)). The automaton \(A\) implements the synchronized product of \(A_1\) and \(A_2\), and keeps one bit \(b(v_1, v_2)\) for each pair \((v_1, v_2)\) of weights \(v_1 \in V_1\) and \(v_2 \in V_2\). If a transition in \(A_i\) for some \(i \in \{1, 2\}\) has weight less than \(v_i\), then the bit \(b(v_1, v_2)\) is set to \(\perp\), otherwise it is set to \(\top\). The weight of a transition in \(A\) is the largest value of \(v_1 + v_2\) such that the corresponding bit \(b(v_1, v_2)\) is \(\top\). Formally, we define:

- \(Q = Q_1 \times Q_2 \times [V_1 \times V_2 \to \{\top, \perp\}]\);
- \(q_1 = \langle q_1^1, q_2^2, b_1 \rangle\) where \(b_1(v_1, v_2) = \perp\) for all \((v_1, v_2) \in V_1 \times V_2\);
- For each \(\sigma \in \Sigma\), the set \(\delta\) contains all the triples \((\langle q_1, q_2, b \rangle, \sigma, \langle q_1', q_2', b' \rangle)\) such that \((q_1, q_2, b) \in \delta_i\) (\(i = 1, 2\)), and for all \((v_1, v_2) \in V_1 \times V_2\), we have \(b'(v_1, v_2) = \top\) if \(\gamma_i(\langle q_1, q_2, b \rangle) \geq v_i\) for \(i = 1, 2\), and otherwise \(b'(v_1, v_2) = \perp\).
- \(\gamma\) is defined by \(\gamma(\langle q_1, q_2, b \rangle, \sigma, \langle q_1', q_2', b' \rangle) = \max\{\gamma_1 + \gamma_2 + v_1 + v_2 \mid b'(v_1, v_2) = \top\}\) where \(\gamma_1\) is the minimal weight in \(V_1\) and \(\gamma_2\) is the minimal weight in \(V_2\).

The result for DLinf follows from the fact \(A\) is deterministic if \(A_1\) and \(A_2\) are deterministic. \(\square\)

Theorem 4.21. The (non)deterministic Disc-automata are closed under sum, with cost \(O(n_1 \cdot n_2)\).

Sketch. It is easy to see that the synchronized product of two \(N\text{Disc}\) (resp. \(D\text{Disc}\)) defines the sum of their languages, if the weight of a joint transition is defined as the sum of the weights of the corresponding transitions in the two \(N\text{Disc}\) (resp. \(D\text{Disc}\)). \(\square\)

Theorem 4.22. The (non)deterministic LimAvg-automata are not closed under sum.

Proof. Consider the alphabet \(\Sigma = \{a, b\}\), and consider the DLavg-definable languages \(L_a\) and \(L_b\) that assigns to each word \(w\) the long-run average number of \(a\)'s and \(b\)'s in \(w\) respectively. Let \(L_+ = L_a + L_b\). Assume that \(L_+\) is defined by a NLavg \(A\) with set of states \(Q\) (we assume w.l.o.g that every state in \(Q\) is reachable).

First, we claim that from every state \(q \in Q\), there is a run of \(A\) over \(a^{|Q|}\) that visit a cycle \(C^*\) with average weight 1. To see this, notice that from every state \(q \in Q\), there is an infinite run \(b\) of \(A\) over \(a^\omega\) whose value is 1 (since \(L_+(w \cdot a^\omega) = 1\) for all finite words \(w\)). Consider the following decomposition of \(b\). Starting with an empty stack, we push the states of \(\rho\) onto the stack as soon as all the states on the stack are different. If the next state is already on the stack, we pop all the states down to the repeated state thus removing a simple cycle of \(\rho\). Let \(C_1, C_2, \ldots\) be the cycles that are successively removed. Observe that the height of the stack is always at most \(|Q|\). Let \(\beta\) be the largest average weight of the cycles \(C_i\), \(i \geq 1\), and let \(\alpha_{\max}\) be the largest weight in \(A\). Assume towards contradiction that \(\beta < 1\). Then, for all \(n > 0\), the value of the prefix of length \(n\) of \(\rho\) is at most:

\[
\frac{\alpha_{\max} \cdot |Q| + \beta \cdot \sum_{i=1}^{k_n} |C_i|}{n}
\]

where \(k_n\) is the number of cycles that have been removed from the stack when reading the first \(n\) symbols of \(\rho\). Hence, the value of \(\rho\) is at most \(\beta < 1\), which is a contradiction. Therefore, the average weight of some cycle \(C^* = C_i\) is exactly \(\frac{1}{2}\) (there are finitely many
different cycles as they are simple cycles). Since the height of the stack is at most $|Q|$, the cycle $C^*$ is reachable in at most $|Q|$ steps.

Second, it can be shown analogously that from every state $q \in Q$, there is a run over $b^{i|Q|}$ that visit a cycle $C^*$ with average weight 1.

Third, for arbitrarily small $\epsilon > 0$, consider the word $w$ and the run $\rho$ of $A$ over $w$ generated inductively by the following procedure: $w_0$ is the empty word and $\rho_0$ is the initial state of $A$. We generate $w_{i+1}$ and $\rho_{i+1}$ from $w_i$ and $\rho_i$ as follows: (i) generate a long enough sequence $w'_{i+1}$ of $a$'s after $w_i$ such that the average number of $b$'s in $w_i \cdot w'_{i+1}$ falls below $\epsilon$ and we can continue $\rho_i$ and reach within at most $|Q|$ steps (and then repeat $k$ times) a cycle $C$ of average weight 1 and such that the average weight of this run prolonged by $|Q|$ arbitrary transitions is at least $1 - \epsilon$, i.e.

$$\frac{\gamma(\rho_i) + k \cdot |C| + 2\alpha_{\min} \cdot |Q|}{|\rho_i| + k \cdot |C| + 2 \cdot |Q|} \geq 1 - \epsilon$$

where $\alpha_{\min}$ is the least weight in $A$. This is possible since $k$ can be chosen arbitrarily large. Let $\rho_{i}'$ be the prolongation of $\rho_i$ over $w'_{i+1}$; (ii) then generate a long enough sequence $w''_{i+1}$ of $b$'s such that the average number of $a$'s in $w_i \cdot w'_{i+1} \cdot w''_{i+1}$ falls below $\epsilon$ and as above, we can construct a continuation $\rho_{i}''$ of $\rho_i'$ whose average weight is at least $1 - \epsilon$ (even if prolonged by $|Q|$ arbitrary transitions); (iii) the word $w_{i+1} = w_i \cdot w'_{i+1} \cdot w''_{i+1}$ and the run $\rho_{i+1}$ is $\rho_{i}'''$. The word $w$ and the run $\rho$ are the limit of these sequences. We have $L_0(w) = L_0(w) = 0$ and thus $L_+(w) = 0$, while the value of $\rho$ is at least $1 - \epsilon$, a contradiction.
